12.2: Nitric Oxide

The major objective of this lecture is to describe the effects of inhaling low levels of nitric oxide (NO) on the hemodynamic and gas exchange function of both the normal and diseased lung. Considerable attention will be paid to safety and hazards of inhaled NO therapy. During the past few years remarkable progress has been made in understanding the NO guanylate cyclase signal transduction system. NO has been given considerable clinical investigation in pulmonary artery hypertension and adult respiratory distress syndrome (ARDS) patients. This lecture concentrates on this area of clinical research.

Pulmonary hypertension with severe hypoxemia may complicate the care of patients with diseases such as chronic pulmonary hypertension, ARDS, chronic respiratory failure, congenital heart disease, and after cardiopulmonary bypass.

Numerous vasodilator therapies aimed at reducing pulmonary hypertension have been tested in these patients. Systemic vasodilation and hypotension occur with all the currently available intravenous vasodilators tested in dosages sufficient to reduce the pulmonary artery pressure. In addition, intravenous infusions of systemic vasodilators such as nitroprusside or prostacyclin (PGI2) markedly increase the venous admixture (1,2).

NITRIC OXIDE

In 1987, the gaseous molecule NO was identified as an endothelium derived relaxing factor (EDRF) (3,4). NO is an ideal local transcellular messenger because of its small size, lipophilic nature, and short duration of action (5) and its numerous functions in various tissues have been reviewed (6). In vascular endothelial cells, NO is synthesized from the terminal guanidine nitrogen of L-arginine and diffuses rapidly into subjacent vascular smooth muscle (7). There, NO binds to the heme iron complex of soluble guanylate cyclase. The resulting nitrosylheme activates guanylate cyclase, stimulating the production of cyclic guanosine 3’,5’- monophosphate (cGMP) and subsequently relaxing vascular smooth muscle (7,8). When NO diffuses into the intravascular space, its biologic activity is limited by avid binding to hemoglobin.
Interestingly, the nitroso vasodilators we have used for decades, such as nitroglycerin and nitroprusside, act by releasing NO (9).

Endothelium-dependent relaxation in pulmonary arteries occurs in response to a variety of physical and pharmacologic stimuli (10). Endogenous NO can be measured in the exhalation of rabbits, guinea pigs, and humans (11). In normal lungs, however, baseline pulmonary vascular tone is very low and the administration of acetylcholine or the addition of exogenous NO has little effect on pulmonary vascular resistance (12 - 14). In patients with pulmonary hypertension, on the other hand, acetylcholine infusion or NO inhalation can reduce pulmonary vascular resistance (12,13). It is possible that in some acute and chronic pulmonary hypertensive states, such as ARDS, or chronic pulmonary hypertension, the production of endogenous NO is impaired (15,16). This might produce further vasoconstriction and foster platelet aggregation (17). Evidence supporting this hypothesis is indirect at this time. Such patients may have an intact response to inhaled NO even though their response to intravenous acetylcholine is impaired (18).

NO Inhalation in ARDS

We hypothesized that inhaled NO should diffuse into the pulmonary vasculature of ventilated lung regions and cause relaxation of pulmonary vascular smooth muscle, thereby decreasing pulmonary hypertension in ARDS (19,20). Since the NO is inhaled, the gas should be distributed predominantly to well-ventilated alveoli and not to collapsed or fluid-filled areas of the lung. In the presence of increased vasomotor tone, selective vasodilation of well-ventilated lung regions should cause a "steal" or diversion of pulmonary artery blood flow towards well-ventilated alveoli, improving the matching of ventilation to perfusion and improving arterial oxygenation during ARDS. Such an effect would be in marked contrast to the effects of intravenously administered conventional vasodilators (such as nitroprusside, nitroglycerin, or prostacyclin). These intravenous agents also decrease PA pressure, but by nonselectively dilating the pulmonary vasculature, they augment blood flow to nonventilated areas, thereby increasing right-to-left shunting and reducing the PaO2. Also unlike available intravenous vasodilators, inhaled NO, because it is avidly bound to hemoglobin and rapidly inactivated, should not produce systemic vasodilation.

Rossaint and coworkers compared the effects of NO inhalation (18 and 36 parts per million (ppm)) to intravenously infused prostacyclin in nine patients with ARDS (21). NO selectively reduced mean pulmonary artery pressure from 37 + 3 to 30 + 2 mmHg (mean + SE). Oxygenation improved due to a decreased venous admixture (QVA/Qt). During NO breathing, the PaO2/FIO2 ratio increased from 152 + 15 mmHg to 199 + 23 mmHg. While the intravenous infusion of prostacyclin also reduced pulmonary artery pressure, mean arterial pressure and PaO2 decreased as QVA/Qt increased. Subsequent reports documented that inhalation of lower concentrations of NO (< 20 ppm) effectively reduced pulmonary artery pressure and improved PaO2 (22 - 25). Even very small inhaled concentrations (as low as 250 parts per billion NO) may be effective in some patients (26). Right ventricular ejection fraction may increase in some patients responding to inhaled NO, suggesting that the observed decreases of pulmonary artery pressure may be hemodynamically important (24,25).

A marked variation has been reported for the hemodynamic and respiratory effects of NO inhalation, both among patients and within the same patient at different times in their illness (22,27,28). It is possible that preexisting pulmonary disease as well as the concomitant administration of other vasoactive drugs may contribute to the observed variability. In general, the baseline level of pulmonary vascular resistance appears to predict the degree of pulmonary vasoconstriction reversible by NO inhalation. Those with the greatest degree of pulmonary hypertension appear to
respond best to NO inhalation (22,28). Dellinger recently reported a dose-response analysis of a randomized trial of NO in 177 ARDS patients (29), a trial which was too small to obtain significant outcome data.

Tachyphylaxis has not been observed even when NO inhalation was continued for up to 53 days (21). Pulmonary artery pressure and PaO2 quickly return to baseline values, however, after discontinuation of the gas. Occasionally, sudden discontinuation of inhaled NO can produce problematic pulmonary vasoconstriction and possibly bronchoconstriction (22,30,31). The reason for this is unclear. Possibly, the addition of exogenous NO may decrease NO synthase activity (32) or increase tissue cGMP phosphodiesterase activity.

The vasoconstrictor almitrine besylate has been given intravenously to enhance pulmonary vasoconstriction during NO breathing. This agent has further reduced Qs/Qt in ARDS in combination with NO inhalation (33).

**NO Inhalation in Neonatal Respiratory Failure**

At birth, there is a sustained decrease of pulmonary vascular resistance and an increase of pulmonary blood flow, in part due to increasing oxygen tensions. If this does not occur, persistent pulmonary hypertension of the newborn (PPHN) may result. Persistent pulmonary hypertension of the newborn is a syndrome characterized by an increased pulmonary vascular resistance, increased right-to-left shunting across the ductus arteriosus and foramen ovale, and severe hypoxemia. Extracorporeal membrane oxygenation (ECMO) is often used to support these infants, because conventional vasodilator therapy is limited by severe systemic hypotension and may reduce PaO2 by increasing right-to-left shunting. It has been hypothesized that endogenous production of NO by the pulmonary vasculature might be decreased in PPHN. If so, then inhaled NO might provide an effective therapy for these severely ill infants (34, 35). Multiple small clinical studies of NO inhalation have been performed in neonates, infants, and children with various types of acute respiratory failure. In general, pulmonary hypertension is reduced and systemic arterial oxygenation is improved with inhalation of less than 20 ppm NO. Nitric oxide inhalation in babies with PPHN and hypoxic respiratory failure has been studied in randomized multicenter trials (36,37). As in adults, however, the response is variable. In the neonatal lung, the degree of improvement with NO appears to depend upon the presence of mature surfactant.

Laboratory studies of the neonatal pulmonary circulation have also documented that inhaled nitric oxide is an effective pulmonary vasodilator (38). Additionally, important experimental evidence is accumulating that the inhalation of nitric oxide attenuates chronic hypoxic pulmonary vascular remodeling of the pulmonary circulation (39,40). Conceivably, inhaled nitric oxide therapy might be used to limit the chronic pulmonary vascular changes which accompany neonatal acute respiratory failure.
